Trial of interest: Multi-Arm Multi-Stage (MAMS) trial

Stopping boundaries at each stage for treatment k

- $Z_{k,0,j} > u_j$.
- $Z_{k,0,j} < l_j$.
- $l_j \leq Z_{k,0,j} \leq u_j$.

Our assumptions and notation:

- Equal allocation ratio.
- Primary outcome of the i^{th} patient on treatment k , $X_{k,i} \sim \mathcal{N}(\mu_k, \sigma^2)$.
- n_j the number of patients recruited on each treatment by the end of stage j .
- Pre-defined stopping boundaries.

Advantages to including multiple treatments:

- Shared trial infrastructure.
- Shared control group.
- Less administrative and logistical effort.
- Enhanced recruitment.
- Reduced cost and time.

But what if a treatment is found superior after the first stage

But what if a treatment is found superior after the first stage

But what if a treatment is found superior after the first stage

Should this treatment become our new control for the rest of the trial if it is becoming the new standard of care?

Assuming we stay with the predefined boundaries and sample size then a question for powering the study is should we:

- Use all the data?
- Use only the data post the change?

What is going to be tested

Test the null hypotheses $H_{k'k}$ of $\mu_k \leq \mu_{k'}$.

All the data is used:

$$Z_{k,k',j} = \frac{\sum_{i=1}^{n_j} X_{k,i} - \sum_{i=1}^{n_j} X_{k',i}}{\sigma \sqrt{2(n_j)}}.$$

Only the data post the change is used:

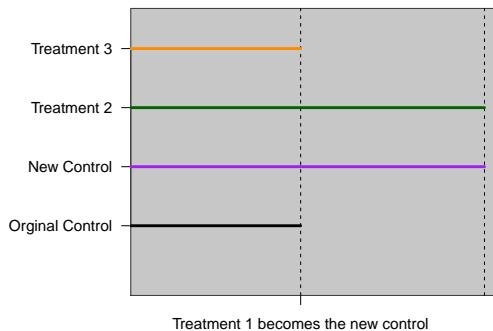

$$Z_{k,k',j,j'}^* = \frac{\sum_{i=n_{j'}+1}^{n_j} X_{k,i} - \sum_{i=n_{j'}+1}^{n_j} X_{k',i}}{\sigma \sqrt{2(n_j - n_{j'})}}$$

where j' defines the stage at which k' became the new control.

Conditional Power

Definition

$P(\text{reject } H_{k'|k} | k' \text{ is the current control from stage } j' \text{ and } k \text{ is still being tested}).$

Theorem

If a treatment k' become the control at stage 1 and $u_2 \geq 0$ then keeping the historic data is detrimental to the conditional power of treatment k^ .*

It is worth keeping the historic data if:

$$Z_{k^*,k',j'} > \frac{u_j[\sqrt{n_j} - \sqrt{n_j - n_{j'}}]}{\sqrt{n_{j'}}} \geq 0 \quad (1)$$

However $Z_{k^*,k',j'} < 0$ as treatment k' is the new control not treatment k^* .

Motivating example

We consider the design of the TAILoR study (Pushpakom et al., 2015):

- Family wise error control: 5%
- 3 active arms and 1 control arm
- 2 stages for each arm
- Number of patients per arm per stage: 42
- Clinically relevant effect if $\sigma = 1$ is: 0.545
- We choose the triangular stopping boundaries (Whitehead, 1997) found using Magirr et al. (2012)

Conditional power example

Difference in conditional power example

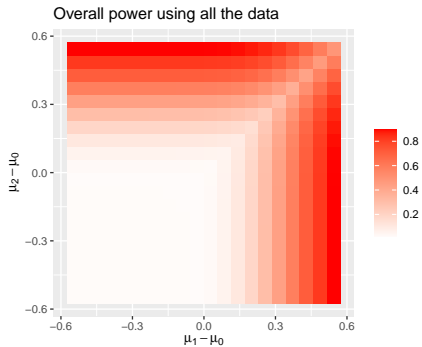

Definition

$P(\text{The treatment } k^* \text{ with the greatest treatment effect, } \mu_{k^*} \geq \mu_k \forall k = 1, \dots, K, \text{ is taken forward when compared to the original control or is found superior to a new control } k')$.

Overall power example

Difference in overall power example

Adding a treatment later

2 cases when a treatment is planned to be added halfway through:

- (i) 2 analyses per treatment.
- (ii) Only one analysis per treatment.

We choose triangular stopping boundaries found using Greenstreet et al. (2021).

Conditional power difference for treatment 3

Overall power using all the data

Overall power difference

All treatments start at the same time

- In most cases conditional power is lower when the pre change data is retained.
- In most cases overall power is lower when the pre change data is retained.

When adding later

- In most cases treatments added at the start have lower conditional power and overall power when the pre change data is retained.
- Even for the later treatments there is no guarantee that keeping the old data will increase the conditional power or overall power.
